1. Introduction

Ocean system is regarded as an open dissipative system connected to the surrounding system (atmosphere and the universe) mainly through heat and salt fluxes. In this viewpoint, the formation of a circulatory structure can be regarded as a process leading to the final equilibrium of the whole system consisting of the ocean system and the surrounding system. In this process, the rate of approach to the equilibrium, i.e. the rate of entropy production by the oceanic circulation, seems to be an important factor. We have so far investigated the relationship between the global (total) entropy production in the ocean system and the formation of the circulatory structure (Shimokawa & Ozawa, 2001, 2002, 2005). In addition, we are also interested in the local (distribution of) entropy production in the ocean system to obtain a complete understanding of the ocean system. The objective of this study is to evaluate the local rate of entropy production in the ocean system by using an oceanic general circulation model.

2. Formulation of entropy production in the ocean system

The global rate of entropy production $\dot{S}$ is calculated in the ocean system such as

$$
\dot{S} = \int \frac{\rho c}{T} \frac{\partial T}{\partial t} F_s \frac{\partial C}{\partial t} + \int \frac{\partial T}{\partial t} (F_h - \alpha k) \int F \ln C dV.
$$

where $\rho$ is the density, $c$ is the specific heat at constant volume, $T$ is the temperature, $\alpha = 2$ is van’t Hoff’s factor representing the dissociation effect of salt into separate ions (Na+ and Cl⁻), $k$ is the Boltzmann constant, $C$ is the number concentration of salt per unit volume of sea water, $F_h$ and $F_s$ are the heat and salt fluxes per unit surface area, defined as positive outward, respectively. The first term on the right hand side represents the rate of entropy increase in the ocean system due to heat transport, and the second term represents that in the surrounding system. The third term represents the rate of entropy increase in the ocean system due to salt transport, and the fourth term represents that in the surrounding system. Overall, Equation (1) represents the rate of entropy of the whole system, i.e. the entropy production due to irreversible process associated with the oceanic circulation.

This expression can be rewritten in a different form with some mathematical transformation such as

$$
\dot{S} = \int \frac{\rho c}{T} \frac{\partial T}{\partial t} \Psi \frac{\partial T}{\partial t} + \int \frac{\partial T}{\partial t} F_h \frac{\partial C}{\partial t} + \int \frac{\partial T}{\partial t} F_s \frac{\partial C}{\partial t} + \int \frac{\partial T}{\partial t} F \ln C dV.
$$

where $F_h$ and $F_s$ are the flux density of heat and salt (vector in three dimensional space), respectively, and $\Psi$ is the dissipation function, representing the rate of dissipation of kinetic energy into heat by viscosity per unit volume of the fluid. The first term on the right-hand side represents the rate of entropy increase by thermal dissipation ($heat$ conduction), the second term is that by viscous dissipation, and the third term is that by molecular diffusion of salt ions.

Since entropy production due to salt transport is negligible for the ocean system (Shimokawa & Ozawa, 2001), the local entropy production can be estimated from the first term in (2) such as

$$
\dot{A} = \frac{\rho c}{T} \frac{\partial T}{\partial t} A_h + \frac{\partial T}{\partial t} A_s + \frac{\partial T}{\partial t} A \ln C dV.
$$

where $A_h$, $A_s$, and $A$ are the horizontal diffusivity, the vertical diffusivity, and the diffusivity function. It is assumed here that $F_h = \Psi = F_s = -k \nabla(T)$, where $k = \rho CD_t$ is thermal conductivity, and $D_t$ is eddy diffusivity ($D_h$ or $D_v$).

GFDL MOM version 2 is used for estimation of entropy production in the ocean system. The model domain is a rectangular basin with a cyclic path, representing an idealized Atlantic Ocean. The horizontal grid spacing is 4 degrees. The depth of the ocean is 4500 m with twelve vertical levels. The horizontal and vertical diffusivities ($D_h$ and $D_v$) are $10^3$ m$^2$s$^{-1}$ and $10^{-4}$ m$^2$s$^{-1}$, respectively. We conducted a spin-up experiment under restoring boundary conditions for 5000 years and obtained a steady state with northern sinking circulation. We calculated the global and local entropy productions for the steady state (see Shimokawa & Ozawa (2001) for the results of global entropy production).

3. Local entropy production in the ocean system

Figure 1 shows the distribution of local entropy production for the steady state as stated above. It can be seen from the zonal average of $A$ (Fig. 1(a)) that entropy production is large in shallow layers at low latitudes. This can be seen also in the zonal–depth average of $A \times dV$ (Fig. 1(c)). On the other hand, it can be seen from the depth average of $A \times dV$ (Fig. 1(b)) that entropy production is large at the western boundaries at mid latitudes. Thus, entropy production is highest at low latitudes as the zonal average, but it is greatest at the western boundaries at mid latitudes as the depth average. It can be seen from the Figures of $A_h$, $A_s$, and $A$ (Fig. 1(d), (g) and (j)) that $A_h$ is large in shallow–intermediate layers at mid latitudes, $A_s$ is large in intermediate layers at mid–high latitudes, and $A$ is large in shallow layers at low latitudes. It can be also seen from the Figures of $A_h \times dV$, $A_s \times dV$ and $A \times dV$ (Fig. 1(e), (f), (h), (i), (k) and (l)) that $A_h \times dV$ is large at the western boundaries at mid latitudes, $A_s \times dV$ is large at mid–high latitudes, and $A \times dV$ is large at low latitudes. In addition, it can be seen that the values of $A_h/A_s \times dV$ are smaller than those of $A_s/A_h \times dV$ and $A/A_s \times dV$. Thus, there are three regions with large entropy production, namely, shallow layers at low latitudes, western boundaries at mid latitudes, and intermediate layers at high latitudes. It can be assumed that the contribution of shallow layers at low latitudes is due to equatorial upwelling, that of western boundaries at mid latitudes is due to western boundary currents, and that of intermediate layers at high latitudes is due to deep water circulation. It can be also seen that high dissipation regions at high latitudes in the northern hemisphere

are reflected in the intermediate layer in the zonal averages of $A \times dV$ and $A_y \times dV$, and the peak of northern hemisphere is larger than that of southern hemisphere in the zonal-depth averages of $A$ and $A_y$. These features appear to represent the characteristics of the circulation with northern sinking.

Strictly speaking, we should take into account dissipation in a mixed layer and dissipation by convective adjustment for entropy production in the model. The dissipation in a mixed layer can be estimated from the first term in (2) such as

$$B = \frac{\rho c}{\Delta t} \frac{(T_r-T_s)^2}{T^2},$$

where $T_r$ is restoring temperature (see Shimokawa & Ozawa, 2001 for the distribution), $T_s$ is sea surface temperature in the model, and $\Delta t$ is the relaxation time of 20 days. It is assumed here that $F_h = -k \text{grad}(T) = -\rho c D_M \text{grad}(T)$, where $k = \rho c D_M$ is thermal conductivity, $D_M = \Delta z r^2 / \Delta t$, is diffusivity in the mixed layer, and $\Delta z$ is a mixed layer thickness of 25 m. The estimated value of $B$ is lower than that of $A$ by three or four orders and is negligible.

The dissipation by convective adjustment can be estimated from the first term in (1) such as

$$C = \frac{\rho c}{\Delta t} \frac{(T_b-T_a)}{T_b},$$

where $T_b$ is temperature before convective adjustment, $T_a$ is temperature after convective adjustment, and $\Delta t$ is the time step of 5400 seconds. $T_b$ is identical to $T_a$ at the site where convective adjustment has not occurred. We have confirmed that the value of $C$ is negligible in the steady state of this oceanic general circulation.
